ABSTRACT
Consider a single server system serving a multiclass population. Some popular scheduling policies for such system are the discriminatory processor sharing (DPS), discriminatory random order service (DROS), generalized processor sharing (GPS) and weighted fair queuing (WFQ). In this paper, we propose two classes of policies, namely MPS (multiclass processor sharing) and MROS (multiclass random order service), that generalize the four policies mentioned above. For the special case when the multiclass population arrive according to Poisson processes and have independent and exponential service requirement with parameter $\mu_i$, we show that the tail of the sojourn time distribution for a class $i$ customer in a system with the MPS policy is a constant multiple of the tail of the waiting time distribution of a class $i$ customer in a system with the MROS policy. This result implies that for a class $i$ customer, the tail of the sojourn time distribution in a system with the DPS (GPS) scheduling policy is a constant multiple of the tail of the waiting time distribution in a system with the DROS (respectively WFQ) policy.

1. INTRODUCTION
Consider a single server system with multiclass customers. Some commonly used scheduling policies in such multiclass system are DPS, DROS, GPS and WFQ. A quick overview of these policies is as follows. Policies like GPS and DPS are variants of the processor sharing policy where the server can serve multiple customers from the system simultaneously. In case of GPS, a separate queue is maintained for each customer class and the total service capacity of the server is shared among customers of the different classes in proportion to predefined weights $p_i$. The GPS scheduling policy is often considered as a generalization of the head-of-line processor sharing policy (HOLPS) as described in [8, 16, 17]. (Refer [18, 19] for details about HOLPS). As a generalization of HOLPS, GPS maintains a FIFO scheduling policy within the queue of each class and only the head-of-line customers of different classes are allowed to share the processor. The share of the server for a head-of-line Class $i$ customer is proportional to the weight $p_i$ and is independent of the number of other customers in the queue. The service rate received by the customer is precisely given by $\phi_j = 1$ if the queue has at least one class $j$ customer and $\phi_j = 0$ otherwise. Refer Parekh and Gallager [13], Zhang et al. [14] for an early analysis of the model.

In case of DPS, the total service capacity is shared among all the customers present in the system and not just among the head-of-line customers of different classes. The share of the server for a customer of a class is not only in proportion to the class weight, but also depends on the number of multiclass customers present in the queue. In particular, a Class $i$ customer in the system is served at a rate of $\frac{\phi_i n_i}{\sum_{j=1}^{N} p_j n_j}$ where $n_j$ denotes the number of Class $j$ customers in the system. The DPS system was first introduced by Kleinrock [7] and subsequently analyzed by several authors [3, 15, 10, 9, 11]. See [1] for a survey of various results on DPS.

The DROS and WFQ scheduling policies are also characterized by an associated weight for each customer class. However these policies are not a variant of the processor sharing policies and hence their respective server can only serve one customer at a time. The DROS and WFQ policies differ in their exact rule for choosing the next customer. In the DROS policy, the probability of choosing a customer for service depends on the weights and the number of customers of the different classes in the queue. A Class $i$ customer is thus chosen with a probability of $\frac{\phi_i n_i}{\sum_{j=1}^{N} p_j n_j}$ where $n_j$ denotes the number of Class $j$ customers waiting in the system for service. DROS policy is also known as relative priority policy and was first introduced by Haviv and van der Wal [9]. For more analysis of this policy we refer to [5, 12]. In the WFQ policy, a separate queue for each class is maintained and the next customer is chosen randomly from among the head-of-line customers of different classes. As in case of the GPS scheduling policy, a FIFO scheduling policy is used within each queue for a class. WFQ can be seen as a packetised version of GPS and the probability of choosing a head-of-line Class $i$ customer for service is given by $\frac{\phi_i}{\sum_{j=1}^{N} \phi_j n_j}$ where $\phi_j$ is as defined earlier. Refer Demers [16] for the detailed analysis of the WFQ policy.

It is interesting to note that for a Class $i$ customer, the service rate received in DPS and the probability of being chosen next for service in case of DROS is given by $\frac{p_i}{\sum_{j=1}^{N} p_j n_j}$. Similarly, the service rate received in GPS and the probability of being chosen next for service in case of WFQ is $\frac{\phi_i}{\sum_{j=1}^{N} \phi_j n_j}$. This similarity in the scheduling rules motivates us to compare the tail of the waiting time and sojourn time distributions of the multiclass customers with these scheduling policies. Assuming identically distributed service requirements for all customers, we will show that the tail of the
waiting time distribution of a Class $i$ customer in a system with DROS (WFQ) scheduling policy is $\rho$ times the tail of the sojourn time distribution of any Class $i$ customer with DPS (resp. GPS) scheduling policy. This is a generalization of [4], where the equivalence has been established between single-class processor sharing and random order service discipline.

**Organization:** In the next section, we introduce a generalized notion of multiclass processor sharing (MPS) and random order service (MROS) policies. The DPS, GPS, DROS and WFQ policies will turn out to be special cases of MPS and MROS. In Section 3, we show that the tail of the sojourn time distribution of a Class $i$ customer with MPS scheduling is equivalent to the tail of the waiting time distribution of a Class $i$ customer with MROS policy. As a special case, this proves the mentioned equivalences among the four multiclass scheduling policies.

**Notation:** We use $N$ to denote the total number of customer classes in the system. Let $\lambda_i$ denote the arrival rate for a Class $i$ customer, $i = 1 \ldots N$. Let $\sum_{i=1}^{N} \lambda_i = \sum \lambda$ and $\rho = \sum_{i=1}^{N} \rho_i$. Further, let $p_i$ denote a weight parameter associated with a Class $i$ customer.

**Assumptions:**

We assume that the service requirement of each customer is independent and exponentially distributed with rate $\mu$. Thus the service requirements are independent of their class. We also assume that customers from different classes arrive according to independent Poisson processes. For the purpose of stability, we assume that $\sum \lambda < \mu$.

2. **Generalized Multiclass Scheduling Policies**

In this section, we will describe two multiclass scheduling policies that are a generalization of policies such as DPS, DROS, GPS and WFQ. The two policies are based on the processor sharing and random order service mechanism and will be labeled as MPS and MROS respectively.

The MPS scheduling policy is a multiclass processor sharing policy where the server can serve multiple customers simultaneously. A separate queue for each customer class is maintained and a FIFO scheduling policy is used within each queue of a class. The MPS scheduling policy is parameterized by a vector $\vec{\lambda} = (\lambda_1, \ldots, \lambda_N)$ that characterizes the maximum permissible number of customers of each class that can be served simultaneously with other customers. We shall henceforth use the notation MPS($\vec{\lambda}$) when we talk about an MPS policy with parameter $\vec{\lambda}$. Let $n_i$ denote the instantaneous number of Class $i$ customers in the queue and $\vec{n} := (n_1, \ldots, n_N)$ denotes the corresponding state in the MPS system. Let $\beta_i(\vec{n})$ denote the number of Class $i$ customers under service when the state of the MPS system is $\vec{n}$. Then, clearly $\beta_i(\vec{n}) = \min(n_i, \alpha_i)$. In other words, if $n_i < \alpha_i$, then all the Class $i$ customers present in the queue are being served simultaneously for $i = 1, \ldots, N$. However if $n_i > \alpha_i$, then only the first $\alpha_i$ customers of Class $i$ in its queue are served simultaneously. It should be noted that due to the FIFO policy within each queue of a class, only the first $\beta_i(\vec{n})$ customers in the queue are served at any time. To lighten some of the notation, we shall drop the dependence on $\vec{n}$ and use only $\beta_i$ when the context is clear. For an MPS($\vec{\lambda}$) scheduling policy in state $\vec{n}$, the service rate received by a particular Class $i$ customer which is in service is given by $\frac{p_i}{\sum_{j=1}^{N} p_j \alpha_j}$. When $\alpha_i = \infty$, for $i = 1 \ldots N$, the corresponding scheduling policy will be denoted by MPS($\infty$). In this case, $\beta_i = \min(n_i, \infty) = n_i$ and therefore MPS($\infty$) corresponds to the DPS scheduling policy. Similarly if $\vec{\epsilon} = (1, \ldots, 1)$, then MPL($\vec{\epsilon}$) corresponds to the GPS scheduling policy where only the head-of-line customers of each class can be served.

In a similar manner, we can define the MROS($\vec{\lambda}$) scheduling policy where $\vec{\alpha} = (\alpha_1, \ldots, \alpha_N)$ denotes the vector of multiclass customers from which the subsequent customer is chosen for service. As in case of the MPS policy, note that a separate FIFO queue for each customer class is also maintained for the MROS system. At any given time, the first $\beta_i = \min(n_i, \alpha_i)$ customers are candidates for being chosen for service while the remaining $n_i - \beta_i$ customers have to wait for their turn. Note that the state $\vec{n}$ for an MROS($\vec{\lambda}$) scheduling policy denotes the vector of waiting multiclass customers present in the system. In the MROS($\vec{\lambda}$) system, a Class $i$ customer within the first $\beta_i$ customers in its queue will be chosen next for service with probability $\frac{p_i}{\sum_{j=1}^{N} p_j \beta_j}$. As in case of the MPS scheduling, MROS($\infty$) corresponds to the DROS policy whereas MROS($\vec{\epsilon}$) corresponds to the WFQ policy.

**Remark 1:** A policy closely related to the MPS discipline is the limited processor sharing (LPS) policy. LPS is a single class processor sharing policy parameterized by an integer $c$ where $c$ denotes the maximum number of customers that can be served simultaneously. Here $c = \infty$ corresponds to the processor sharing policy whereas $c = 1$ corresponds to FCFS policy. LPS can also be viewed as a special case of the MPS policy when there is a single service class for the arriving customers. See [2, 20] for more details about the LPS-$c$ policy.

Having introduced the generalized multiclass scheduling policies, we shall now establish an equivalence relation between the tail of the sojourn time distribution of a Class $i$ customer in MPS system with the tail of the waiting time distribution of a Class $i$ customer in MROS system.

3. **Comparing the Sojourn and Waiting Time Distributions in MPS and MROS**

The analysis in this section is inspired from that in [4] where a similar result is established for the case of a single class of population. For a given state of $\vec{n} = (n_1, \ldots, n_N)$, define $n := \sum_{i=1}^{N} n_i$. Let random variable $S_i(\vec{\alpha}, \vec{n})$ denote the conditional sojourn time experienced by an arriving Class $i$ customer that sees the MPS($\vec{\lambda}$) system in state $\vec{n}$. The corresponding unconditional random variable will be denoted by $S_i(\vec{\alpha})$. We shall occasionally use the notation MPS($\vec{\alpha}$, $\vec{n}$) to denote the MPS($\vec{\lambda}$) system with $\vec{n}$ customers. Along similar lines, let the random variable $W_i(\vec{\alpha}, \vec{n})$ denote waiting time (time until chosen for service) experienced by an arriving Class $i$ customer that sees the MROS($\vec{\lambda}$) system in state $\vec{n}$, i.e., it sees a vector of $\vec{n}$ waiting customers in the system. This system will be often denoted as MROS($\vec{\alpha}$, $\vec{n}$) and the unconditional random variable will be denoted by $W_i(\vec{\alpha})$. Let $\mathbb{P}$ and $\mathbb{P}^*$ denote the probability distribution of the random variables $S_i(\vec{\alpha}, \vec{n})$ and $W_i(\vec{\alpha}, \vec{n})$ respectively.
that since these distributions on \( \bar{n} \) have been suppressed for notational convenience.) We now state the main result of this paper.

**Theorem 1.** \( \rho P(S_i(\bar{n}) > t) = P(W_i(\bar{n}) > t) \) for \( i = 1, \ldots, N \).

**Proof.** As in [4], our aim is to first provide a coupling \( \left( \bar{S}_i(\bar{n}), \bar{W}_i(\bar{n}) \right) \) with the corresponding law denoted by \( \bar{P} \) such that

1. \( \bar{S}_i(\bar{n}) \overset{\bar{P}}{=} S_i(\bar{n}) \) and \( \bar{W}_i(\bar{n}) \overset{\bar{P}}{=} W_i(\bar{n}) \)
2. \( \bar{P} \left( \bar{S}_i(\bar{n}) \neq \bar{W}_i(\bar{n}) \right) = 1 \)

The second requirement will help us to show that the two distributions \( P \) and \( \bar{P} \) are equal. This follows from the coupling inequality (see [21] for more on coupling inequalities)

\[
\|P - \bar{P}\| \leq 2\bar{P} \left( \bar{S}_i(\bar{n}) \neq \bar{W}_i(\bar{n}) \right) . \tag{1}
\]

Such a coupling is precisely obtained as follows.

Consider two tagged Class i customers X and Y that arrive to a MPS(\( \bar{n} \)) and a MROS(\( \bar{n} \)) system respectively. This means that at the arrival instant of customer X in the MPS(\( \bar{n} \)) system, there are \( n_i \) Class i customers already present in the system. Similarly, at the arrival instant of customer Y in MROS(\( \bar{n} \)), there are \( n_i \) customers of Class i that are waiting for service in the queue. Recall that \( \bar{\beta} = (\beta_1, \ldots, \beta_N) \) where \( \beta_i \) in the MPS system denotes the number of Class i customers that are receiving service. In the MROS system, \( \beta_i \) denotes those (waiting) Class i customers from which the next customer could be chosen. Note that since \( \sum_{i=1}^{N} n_i = n \), with the arrival of customer X, the MPS(\( \bar{n} \)) system has \( n+1 \) customers. Similarly, with the arrival of customer Y, the MROS(\( \bar{n} \)) system has \( n+2 \) customers of which one customer is in service and the remaining \( n+1 \) customers (including customer Y) are waiting for service. We will now specify the rule for forming the required coupling. Since the customers can be distinguished by their class index and also the position in their respective queues, we couple the \( n+1 \) customers in MPS(\( \bar{n} \)) with the \( n+1 \) waiting customers in the MROS(\( \bar{n} \)) system based on their class and queue position. The coupling must be such that the coupled customers belong to the same class and invariably have the same queue position in their respective queues. It goes without saying that the tagged customers X and Y are also coupled. As in [4], we also couple the subsequent arriving customers and let \( D_1, D_2, \ldots \) denote i.i.d random variables with an exponential distribution of rate \( \mu \). These random variables correspond to service times of a customer in service in MROS(\( \bar{n} \)). At the service completion epoch, pick a pair of coupled customers randomly. This random picking is with a distribution such that the chosen pair is of Class i with probability \( \frac{\beta_i(\bar{n})}{\sum_{j=1}^{N} \beta_j(\bar{n})} \). When the randomly chosen pair is of Class i, a class i customer departs from the MPS system while such a customer is taken for service in the MROS system. This process is repeated till the tagged pair (X, Y) leaves the system. Clearly, this joint probability space is so constructed that the random variables \( \bar{S}_i(\bar{n}) = \bar{W}_i(\bar{n}) \) \( \bar{P} \)-a.s. From Eq. (1), this implies that

\[
\bar{S}_i(\bar{n}) \overset{\bar{P}}{=} \bar{W}_i(\bar{n}). \tag{2}
\]

Now let random vectors \( \mathbf{N}^{\text{MPS}} \) (resp. \( \mathbf{N}^{\text{MROS}} \)) denote the vector of multiclass customers present in the system in steady state (resp. waiting in the system in steady state in MROS). The subscript 1 in \( \mathbf{N}^{\text{MROS}} \) is used to indicate a busy server. Since the arrival process is Poisson, the unconditional probabilities are given by the following

\[
P(S_i(\bar{n}) > t) = \sum_{\bar{n}} P(\mathbf{N}^{\text{MPS}} = \bar{n}) P(S_i(\bar{n}) > t). \tag{3}
\]

Similarly, we have

\[
P(W_i(\bar{n}) > t) = \sum_{\bar{n}} P(\mathbf{N}^{\text{MROS}} = \bar{n}) P(W_i(\bar{n}) > t). \tag{4}
\]

Now if \( P(\mathbf{N}^{\text{MROS}} = \bar{n}) = \rho P(\mathbf{N}^{\text{MPS}} = \bar{n}) \) is true, then from Eq. (2), the statement of the theorem follows and this would complete the proof. In the following lemma, we shall prove that indeed \( P(\mathbf{N}^{\text{MROS}} = \bar{n}) = \rho P(\mathbf{N}^{\text{MPS}} = \bar{n}) \).

**Lemma 1.** \( P(\mathbf{N}^{\text{MROS}} = \bar{n}) = \rho P(\mathbf{N}^{\text{MPS}} = \bar{n}) \) for \( \bar{n} \) such that \( |\bar{n}| \geq 0 \).

**Proof.** We first simplify the notations as follows. Let \( \pi(\bar{n}) := P(\mathbf{N}^{\text{MPS}} = \bar{n}) \) and \( \hat{\pi}(1, \bar{n}) := P(\mathbf{N}^{\text{MROS}} = \bar{n}) \). Let \( \hat{\pi}(0, 0) \) denote the probability that the MROS system has no customers and is idle. The statement of the lemma now requires us to prove that \( \hat{\pi}(1, \bar{n}) = \rho \pi(\bar{n}) \). To prove this result, consider the balance equation for the MPS system where \( \pi \) shall denote the stationary invariant distribution for the system. The assumption \( \Lambda < \mu \) implies that the underlying Markov process is ergodic and hence the stationary distribution \( \pi \) is unique. For \( \bar{n} \) such that \( |\bar{n}| \geq 0 \), the global balance equations for the MPS(\( \bar{n} \)) system are

\[
(\Lambda + \sum_{i=1}^{N} \left( \frac{\beta_i(\bar{n})}{\sum_{j=1}^{N} \beta_j(\bar{n})} \right) \mu \mathbb{1}_{\{|\bar{n}| > 0\}} \pi(\bar{n}) = \sum_{i=1}^{N} \lambda_i \mathbb{1}_{\{n_i > 0\}} \pi(\bar{n} - e_i)
\]

\[
+ \sum_{i=1}^{N} \left( \frac{\beta_i(\bar{n} + e_i)}{\sum_{j=1}^{N} \beta_j(\bar{n} + e_i)} \right) \mu \pi(\bar{n} + e_i).
\]

Now since

\[
\sum_{i=1}^{N} \left( \frac{\beta_i(\bar{n})}{\sum_{j=1}^{N} \beta_j(\bar{n})} \right) = 1,
\]

the balance equations can be written as

\[
(\Lambda + \mu \mathbb{1}_{\{|\bar{n}| > 0\}}) \pi(\bar{n}) = \sum_{i=1}^{N} \lambda_i \mathbb{1}_{\{n_i > 0\}} \pi(\bar{n} - e_i) \tag{5}
\]

\[
+ \sum_{i=1}^{N} \left( \frac{\beta_i(\bar{n} + e_i)}{\sum_{j=1}^{N} \beta_j(\bar{n} + e_i)} \right) \mu \pi(\bar{n} + e_i).
\]

Similarly, the global balance equations for the MROS(\( \bar{n} \)) system are as follows for \( \bar{n} \) such that \( |\bar{n}| \geq 0 \).
\[(\Lambda + \mu 1_{\{|n|>0\}})\tilde{\pi}(1,n) = \sum_{i=1}^{N} \lambda_i 1_{\{|n|>0\}}(1,n-e_i) + \sum_{i=1}^{N} \left( \frac{\beta_i(\bar{n}+e_i)p_i}{\sum_{j=1}^{N}p_j\beta_j(\bar{n}+e_i)} \right)\mu\tilde{\pi}(1,\bar{n}+e_i) \quad (6)\]

Additionally, the idle system should satisfy
\[\Lambda\tilde{\pi}(0,\bar{0}) = \mu\tilde{\pi}(1,\bar{0}) \quad (7)\]

where \(\tilde{\pi}(0,\bar{0}) = 1 - \rho\) is the probability that the system is empty. Now again, the assumption \(\Lambda < \mu\) implies that the underlying Markov process is ergodic and hence the stationary distribution \(\tilde{\pi}\) is also unique. Therefore, to prove the lemma, it is sufficient to check if the global balance equations for the MROS system given by Eq. (6) are satisfied when \(\tilde{\pi}(1,n) = \rho\tilde{\pi}(\bar{n})\).

Now from Eq. (6) and assuming that \(\tilde{\pi}(1,n) = \rho\tilde{\pi}(\bar{n})\), we have
\[
\begin{align*}
(\Lambda + \mu 1_{\{|n|>0\}})\tilde{\pi}(1,n) - \sum_{i=1}^{N} \lambda_i 1_{\{|n|>0\}}(1,n-e_i) \\
- \sum_{i=1}^{N} \left( \frac{\beta_i(\bar{n}+e_i)p_i}{\sum_{j=1}^{N}p_j\beta_j(\bar{n}+e_i)} \right)\mu\tilde{\pi}(1,\bar{n}+e_i) \\
= (\Lambda + \mu 2_{\{|n|>0\}})\rho\tilde{\pi}(\bar{n}) - \sum_{i=1}^{N} \lambda_i 2_{\{|n|>0\}}\rho\tilde{\pi}(\bar{n}+e_i)
- \sum_{i=1}^{N} \left( \frac{\beta_i(\bar{n}+e_i)p_i}{\sum_{j=1}^{N}p_j\beta_j(\bar{n}+e_i)} \right)\mu\rho\tilde{\pi}(\bar{n}+e_i) = 0.
\end{align*}
\]

The last equality follows from Eq. (5) after dividing throughout by \(\rho\). Similarly,\[A\tilde{\pi}(0,\bar{0}) - \mu\tilde{\pi}(1,\bar{0}) = A\tilde{\pi}(0,\bar{0}) - \mu\tilde{\pi}(0,\bar{0}) = \mu(\rho\tilde{\pi}(0,\bar{0}) - \rho\tilde{\pi}(\bar{0})) = \mu(\rho\tilde{\pi}(0,\bar{0}) - \rho(1 - \rho)) = 0. \quad (8)\]

Here the third equality is from the fact that \(\tilde{\pi}(0,\bar{0}) = (1-\rho)\) is the probability that the MPS(\(\bar{n}\)) system is empty. Clearly, substituting \(\tilde{\pi}(1,n) = \rho\tilde{\pi}(n)\), satisfies the balance equations for the MROS system. Since \(\tilde{\pi}\) is the unique invariant distribution, the statement of the lemma follows.

We now have the following corollary that establishes the desired equivalence between DPS (GPS) and DROS (resp. WFQ) scheduling policies. Note that the result is true only for the case when all customers have identically distributed service requirements. The equivalence result is not true in general when the customer classes differ in their service requirements.

**Corollary 1.**

- \(\rho P(S_i(\bar{e}) > t) = P(W_i(\bar{e}) > t)\)
  where \(S_i(\bar{e})\) denotes the sojourn time of a Class i customer in GPS system and \(W_i(\bar{e})\) denotes the waiting time of a Class i customer in DROS system.

**4. DISCUSSION**

In this paper, we have proposed two multiclass policies, namely MPS and MROS, that generalize some important multiclass policies from the literature. Our policies are parameterized by a vector \(\tilde{\alpha}\) that can be used to control performance metrics like the mean delay or mean waiting time per class. Restricting to the special case where the multiclass customers arrive according to a Poisson process and have independent and exponential service requirements, we show that the tail of the sojourn time distribution for a class \(i\) customer in a system with the MPS policy is a constant multiple of the tail of the waiting time distribution of a class \(i\) customer in a system with the MROS policy. As special cases, we have thus proved the above equivalence between DPS (GPS) and DROS (resp. WFQ) scheduling policies.

It is worth mentioning that Borst et al [4] have shown the sojourn time equivalence between ROS and processor sharing for a more general case when the arrival process is a general renewal process. While our analysis for MPS and MROS assumes a Poisson arrival process, it would be of interest to investigate if our equivalence result is true when the arrival process is a general renewal process. This is part of future work.
