A B S T R A C T

Lattice disorder, electronic Raman scattering, and Fano interaction effects are at the genesis of the Raman spectrum of heavily boron-doped diamond. However, no accurate unified description of this spectrum has been reported yet. In this work, we propose a novel analysis of the Raman spectrum of boron-doped diamond based on classical models of electronic Raman scattering and Fano effect. This new analysis shows that the Raman spectrum of boron-doped diamond results from the combination of electronic Raman scattering and its interaction, i.e., Fano effect, with the diamond phonon density of states and it confirms the 500 cm$^{-1}$ and 1200 cm$^{-1}$ bands originate from the phonon density of states.

1. Introduction

Raman spectroscopy is a fast and nondestructive technique widely used for the characterization of diamonds. Intensities, position and full width at half maximum of Raman peaks are representative of the quality and composition of diamond layers. For instance, heavily boron-doped diamond with metallic electrical conductivity has a characteristic Raman signature with two broad bands at ca. 500 cm$^{-1}$ (B1) and ca. 1200 cm$^{-1}$ (B2) along with a Fano-shaped zone-center phonon (ZCP) peak below 1332 cm$^{-1}$. It is conjectured the Fano-shape results from interaction between discrete diamond zone-center phonon (ZCP) and electronic Raman scattering effects. The majority of studies on the Fano-shaped diamond peak reports a negative value for the Fano asymmetric parameter ($\alpha$) [1–7]. Other authors reported positive values of the Fano asymmetric parameter in layers [2, 8, 9] with boron concentrations close to the metal-insulator transition (Mott transition). However, substitutional isotopic studies have, unambiguously, demonstrated its vibration origin to be related to carbon atoms [1, 11, 12]. It is generally agreed that this band corresponds to a maximum of the diamond phonon density of states (PDoS) [13, 14]. The appearance of this Raman forbidden band is due to the relaxation of the Raman wave vector conservation rule in materials with high lattice disorder [7, 15], i.e., the high concentration of substitutional boron atoms in the diamond lattice. However, this interpretation is not fully satisfactory due to the mismatch between the experimental peak position, the known optical maxima of diamond’s PDoS [16] and contradictory reports of the peak shape: Szirmai et al. presented this peak as symmetrical with a Lorentzian shape [1], whereas Bustarret et al. depicted it as an asymmetric Fano-shaped peak [3, 17]. The broad asymmetric band B1 is empirically modeled with the sum of a Lorentzian and a Gaussian components [18] or a Lorentzian component [1]. It is very sensitive to the boron concentration [19, 20] and it was attributed to vibration modes of boron dimers [18, 21]. However, substitutional isotopic studies have failed to unambiguously confirm this assignment [12, 14]. The purpose of this article is to address these contradictions. Based on classic models of electronic Raman scattering, Fano effect, and analytical methodology we clarify the origin of the Raman spectrum of the boron-doped diamond.

2. Experimental

In order to remove any added complication due to the presence of $sp^3$ carbon phase Raman features, which are present in polycrystalline diamond layers, this study has been carried out on epitaxial boron-doped diamond layers. The studied epitaxial layers were grown on high pressure and high-temperature diamond substrates in a 1.5 kW resonance cavity microwave plasma enhanced chemical vapor deposition system, AX5010 from Seki Diamond Systems, with two different boron
concentrations. Sample S1 was grown with a boron to carbon ratio, in the gas phase, of 4000 ppm on a (100) oriented substrate using deposition conditions reported in ref. [22], whereas sample S2 was grown with a higher boron to carbon ratio of 40,000 ppm on a (111) oriented substrate using deposition conditions reported in ref. [20]. Raman spectra were measured using a LabRam HR spectrometer from Horiba Jobin-Yvon interfaced to an Olympus microscope with a 100× objective and a 50 μm confocal aperture, and a HeNe laser 633 nm (1.96 eV) with 8 mW power. The spectrometer was calibrated using the silicon F₁g peak at 520.2 cm⁻¹ and its spectral response was calibrated using a certified HL-2000 Tungsten Halogen Light Source from Ocean Optics. Raw Raman spectra were corrected for instrumental response, temperature effect and the frequency factor [23–25]. The temperature correction is particularly important in order to observe the broad electronic Raman scattering response. Corrected spectra or reduced Raman (I(ω)) spectra are calculated using Eq. (1) with I(ω) the experimental spectrum, K(ω) the spectrometer response; ω₁ the absolute frequency of laser excitation line, ω the Raman shift, and n(ω, T) the Bose-Einstein distribution.

I(ω) = I(ω). [K(ω). (ω₂ − ω)². ω⁻¹. (n(ω, T) + 1)]⁻¹

3. Results and discussion

Normalized raw and reduced Raman spectrum of both samples are shown in Fig. 1 and Fig. 2, respectively. The raw spectra are characteristic of boron-doped diamond with metallic electrical conductivity with low (sample S1) and high boron concentration (sample S2) [17, 19]. In contrary to sample S2, sample S1 exhibits no measurable band at ca. 500 cm⁻¹. Both reduced spectra retain the characteristic band of boron-doped diamond. They share a broad asymmetric background with a maximum between 1000 and 2000 cm⁻¹ attributed to electronic Raman scattering, a broadband B2 merged with the narrow diamond line, and a broad dip at 1350 cm⁻¹ attributed to Fano antiresonance. The large width of this dip cannot originate only from the antiresonance of the Fano shaped narrow diamond line. We attribute this dip to a combination of the Fano antiresonance of the B2 band and the diamond line. This assumption is supported by the clear asymmetry of the B2 band, which is characteristic for Fano effect, and is consistent with the work of Bustarret et al. [3]. The two Raman spectra exhibit a different curvature at low wavenumbers, i.e., < 500 cm⁻¹. The concavity of S1 spectrum is consistent with electronic Raman scattering whereas the convexity of S2 sample may be attributed to a Fano antiresonance of the B1 band. This assumption is supported by the well-known asymmetry of this band. Based on these observations, we constructed a fitting function to describe the Raman spectrum of boron-doped diamond assuming the interaction of the observed Raman lines with electronic Raman scattering applies to the diamond ZCP phonon line and all other observed bands using well-established model of electronic Raman scattering and Fano effect. This hypothesis is legitimized by the asymmetric nature of the different bands and the broad range of electronic Raman scattering.

To our knowledge and in contrary to metals [26, 27] and heavily doped silicon [28], electronic Raman scattering has not been investigated in boron-doped diamond. In this work, the normalized electronic Raman scattering Iₑ(ω) is modeled using the Eq. (2) used for Raman scattering by intra-band excitations and where ω₂ is the position of the maximum of the electronic Raman scattering spectrum. This equation was shown to satisfactorily describe electronic Raman scattering in conventional elemental metals [27] and highly doped semiconductors [29].

Iₑ(ω) = \frac{2 (ω/ω₂)}{1 + (ω/ω₂)²}

Fano shaped peaks are modeled using the normalized Fano function

\[
F_j(\omega) = \frac{1}{1 + \frac{\omega - \omega_j}{\Gamma_j}} \left( q_j + \varepsilon_j \right)^2
\]

with

\[
\varepsilon_j(\omega) = \frac{\omega - \omega_j}{\Gamma_j}
\]

Based on the assumptions above, the reduced Raman spectrum of boron-doped diamond is fitted using Eq. (5) representing the sum of the different weighted light scattering events: pure electronic Raman scattering and its interaction with the different localized Raman scatterings. \( \Lambda_i \) is the weighted factor of pure electronic Raman scattering and \( \Lambda_i \) are the weighting factor of the different Fano-shaped peaks.

\[
I_j(\omega) = I_j(\omega) \left[ A_j + \sum_i A_i F_j(\omega) \right]
\]

The Raman spectra of diamond samples were fitted with Eq. (5) using the non-linear fitting tool of Origin 2016 © software. The fitting function and its different components are reported in Fig. 2, and the fitting parameter is reported in Table 1. The fitting function satisfactorily models the B2 band, the diamond lines, and antiresonance dip as well as the broad B1 band. It particularly shows that the broad antiresonance dip at 1350 cm\(^{-1}\) is a combination of the diamond ZCP and the B2 bands antiresonances. The Fano asymmetric parameter values of the B2 band are remarkably close to the ones of the ZCP line, which are consistent with values reported in the literature [1–6] and the position and the width of the diamond line are also consistent with our previous report [20]. The fitting peak position of the B2 band (1250 cm\(^{-1}\)) corresponds to the reported maxima of diamond PDoS [16] which supports our analysis and confirms the PDoS origin of this band. Similarly, the fitting peak position (427 cm\(^{-1}\)) and width (90 cm\(^{-1}\)) of the B1 band are comparable with the reported values of the acoustic maximum of PDoS peak measured by Raman spectroscopy on not electrically conductive diamond nanoparticles and disordered diamond [30, 31]. The assignment of the B1 band to a maximum of the acoustic branch of the PDoS is consistent with was already hypothesized by several other authors [7, 32]. This analysis indicates that the difference between the apparent position of the B1 band and the position of the maximum of PDoS in disordered diamond is not only due to phonon confinement but it is also due its interaction with electronic Raman scattering, i.e. Fano effect, conformably with the ZCP line [20]. This analysis is also analogous to Yogi et al. work on silicon nanostructures which report the observation of a size-dependent position asymmetric peak due to acoustic phonons by Raman spectroscopy due to the quantum confinement effect and their interaction with intraband quasi-continuum [33].

4. Conclusion

In summary, we have shown the Raman spectrum of highly boron-doped diamond can be satisfactorily fitted using the combination of well-established electronic Raman scattering and Fano effect models. This analysis shows that not only the diamond ZCP band is Fano-shaped but also the 500 cm\(^{-1}\) and 1200 cm\(^{-1}\) bands. As a result, their apparent position is shifted from their normal position, which corresponds to the acoustic and optical maxima of the phonon density of states in disordered diamond.
